Role of peroxisome proliferator activator receptor-gamma (PPAR-γ) in lung sepsis Usha Q Patel^{1,} Grazia V Clemencet¹, Colleen B Latruffe², Peter A Reddy¹, Qin Chu³, Charlene J Heyman¹, Alice E Griffin^{1*}

Abstract

PPAR-gamma has been implicated in the pathology of numerous diseases including; obesity, diabetes, atherosclerosis, and cancer. PPAR-gamma agonists have been used in the treatment of hyperlipidaemia and hyperglycemia. Two isoforms of PPARG are detected in the human and in the mouse: PPAR-γ1 (found in nearly all tissues except muscle) and PPAR-γ2 (mostly found in adipose tissue and the intestine). In the present study, to directly determine the role of PPARγ in lung sepsis we used PPARγ-knockout and C57/BL6 mice model. Mice are treated with Lipopolysaccharide LPS (0.5 mg/kg, iv) for 6-hours, the plasma and tissue cytokines TNF-α, IL-1β, IL-6, IL-10, MIP-1 and KC are analyzed by ELISA. The infiltrations of the mononuclear cells in the lung tissue and degree of lung tissue injury are examined using immunofluorescent and histopathology staining respectively. In PPARγ-knockout mice, LPS induced more expression of pro-inflammatory cytokines expression, which was associated with a marked monocyte infiltration, tissue injury and elevated lung activity of myeloperoxidase compared with wild type C57/BL6 mice. Present study, suggests that PPARγ has a critical role in attenuate lung sepsis and further study need to elucidate the clinical value.

Key words: PPARγ; LPS; Proinflammatory cytokines; Lung; Immunofluorescent; PPARγ-

knockout mice

Introduction

The family of transcription factors designated peroxisome proliferator-activated receptors (PPARs) has long been studied for its role in regulation of lipid and glucose metabolism [1]. More recently, PPARs' role in immunoregulation has been recognized and is the subject of intense investigation [2]. PPARs are expressed by a variety of cells of the immune system including monocytes, macrophages, B and T lymphocytes, natural killer cells, dendritic cells, neutrophils, eosinophils, and mast cells [3].

PPARs belong to the nuclear hormone receptor superfamily that regulates a multitude of genes [4]. There are three PPARs encoded by separate genes: PPAR*α*, PPAR*β*/*δ*, and PPAR*γ* [5].

American Journal of BioMedicine AJBM 2014;**2**(4): 228–246

Research Article doi: 10.18081/2333-5106/014-04/228-246

The three PPARs differ in their structure, function, and tissue distribution [6]. PPAR*γ* has received significant attention as a key regulator of adipocyte differentiation as well as glucose and lipid homeostasis [1]. PPAR*γ* can be transcribed from three distinct mRNAs, *γ*1, *γ*2, and *γ*3, based on sites of transcription initiation and splicing [4–6]. However, there are only two protein isoforms, PPAR*γ*1 and PPAR*γ*2, as translation of *γ*1 and *γ*3 mRNAs results in indistinguishable proteins [6]. PPAR*γ*1 is the predominant isoform [7]. Whereas expression of PPAR*γ*2 and PPAR*γ*3 mRNAs is restricted [6], PPAR*γ*1 mRNA is expressed fairly ubiquitously [2].

A variety of ligands, natural and synthetic, are capable of stimulating PPAR*γ* activity. Natural PPAR*γ* ligands include saturated and unsaturated fatty acids, eicosanoid derivatives such as 15-deoxy-Δ- prostaglandin J² (15d-PGJ2), and nitrated fatty acids such as nitrated linoleic and oleic acids [8]. Synthetic PPAR*γ* agonists are represented by thiazolidinediones (TZDs) such as pioglitazone, rosiglitazone, troglitazone, and ciglitazone.

In addition, some nonsteroidal anti-inflammatory drugs such as indomethacin, fenoprofen, and ibuprofen can activate PPAR*γ*, although their binding affinity is lower than that of TZDs. In the absence of these agonists, PPAR*γ* remains inactive, bound to a series of corepressors. Upon ligand activation, these corepressors are displaced, allowing PPAR*γ* to heterodimerize with retinoid X receptors and initiate transcriptional control by binding to specific peroxisome proliferator response elements in the promoter regions of target genes [9].

PPAR*γ* agonists may have other activities, though. For example, pioglitazone has been shown to alter mitochondrial function in a PPAR*γ*-independent manner [10] and nitrated fatty acids are electrophiles that alkylate and may inactivate target proteins [3]. These off-target effects may be either helpful or harmful, depending on the context. Additionally, PPAR*γ* agonists are known to upregulate the receptor's expression, which may render the effects of repeated dosing greater than would be anticipated from single-dose results [6].

Recognition that PPAR*γ* is expressed by a variety of immune cells stimulated interest in its immunoregulatory function, especially its anti-inflammatory role [2]. Involvement of PPAR*γ* in several leukocyte functions supports its prominent role in immunoregulation [7]. Protein and mRNA expression and activity of PPAR*γ* are altered during many inflammatory conditions, and such alterations appear to be a significant factor in the pathogenesis of some diseases [12, 13]. We are surrounded by a variety of microbial species and are constantly interacting with them throughout our lives. Some of these microorganisms are commensal or even beneficial, while others are pathogens that can cause significant morbidity and mortality. The innate immune system, characterized by secretion of proinflammatory cytokines and antimicrobial molecules and recruitment of phagocytes, is a major mediator of resistance to infection by pathogenic bacteria.

Compromised or dysregulated immunity can allow development of major illnesses requiring therapeutic intervention, yet in some cases inflammatory responses themselves can become life-threatening. Although many infectious diseases can be controlled by antibacterial drugs,

doi: 10.18081/2333-5106/014-04/228-246

antimicrobial resistance poses a significant threat to our healthcare system worldwide, compromising therapy, complicating treatment, increasing mortality, and resulting in substantial financial costs [14]. Drugs with novel mechanisms of action are therefore urgently needed. Recent advances in our understanding of PPAR*γ*'s role in immunity, infection, and inflammation, as discussed below, offer the opportunity for intervention with a novel approach to bacterial infections. Appropriate antimicrobial therapy will continue to be the standard of care, but adjunctive use of PPAR*γ* agonists or antagonists may reduce the required antibiotic dosages and improve outcomes.

PPAR*γ*'s anti-inflammatory function is also prominent in chronic granulomatous disease (CGD), an inherited disorder in which phagocytes' defective ability to kill certain infectious pathogens results in chronic and recurrent infections and inflammation. In a mouse model of CGD, macrophages demonstrate reduced PPAR*γ* expression and activation and impaired efferocytosis of apoptotic neutrophils during zymosan-induced acute inflammation [15]. Monocytes from human CGD patients similarly show defective efferocytosis [16]. Furthermore, neutrophils and monocytes/macrophages from these CGD mice as well as monocytes from human CGD patients exhibit defects in PPAR*γ*-dependent production of mitochondrial reactive oxygen species (ROS) that contribute to bacterial killing [17]. These defects can be largely restored by PPAR*γ* activation with pioglitazone, given prophylactically or during preexisting inflammation [18], providing further evidence for the antibacterial effect of PPAR*γ* activation. Importantly, the authors showed that pioglitazone is capable of enhancing CGD phagocytes' ability to clear pathogens such as *S. aureus* and *Burkholderia cepacia*, restoring host defense against these pathogens [4]. Furthermore, the PPAR*γ* agonist pioglitazone produced marked clinical improvement in a 5-month-old boy with CGD and multiple severe infections [19]. Significantly improved ROS production was associated with reductions in pathogen burden and improvements in overall clinical condition that allowed curative hematopoietic stem cell transplantation. Although this reflects an unusual setting, these direct clinical results support the ability of PPAR*γ* agonists to upregulate pathogen killing and clearance.

Infections by a variety of bacteria can result in sepsis, in which blood-borne toxins lead to an exaggerated and dysregulated inflammatory response that frequently results in tissue injury [20]. In severe sepsis, potentially lethal septic shock and multiple organ failure become strong possibilities [9]. PPAR*γ* signaling has shown a protective effect in multiple models of sepsis. In the mouse model of lipopolysaccharide- (LPS-) induced sepsis involving pulmonary inflammation and injury, endothelial cell PPAR*γ* (ePPAR*γ*) deficiency intensifies the tissue injury with increased pulmonary edema and capillary permeability, elevated ROS and cytokine/chemokine production, infiltration of neutrophils to the lungs, and expression of inflammation-associated adhesion molecules such as ICAM-1 and PECAM-1. This exacerbation of inflammatory responses in ePPAR*γ*-deficient mice is due to enhanced toll-like receptor-4 (TLR4) expression in the lung tissues and upregulation of TLR4 downstream signaling including the NF-*κ*B pathway [6]. TLR4 signaling has been shown to play a key role

Research Article doi: 10.18081/2333-5106/014-04/228-246

in modulating inflammation/sepsis [6]. In addition to the effects of PPAR*γ* agonists reported by others, Reddy et al. observed that physiologically relevant concentrations of 10-nitro-oleic acid reduce LPS-induced transcription of many inflammatory markers and inhibit neutrophil transmigration *in vitro* [3].

The protective effect of PPAR*γ* activation is also demonstrated in mouse and rat models of polymicrobial sepsis using cecal ligation and puncture (CLP) [7]. Zingarelli et al. found that rats subjected to CLP exhibit reduced PPAR*γ* expression in the lungs and thoracic aortas, increased circulating neutrophils accompanied by reduction in lymphocytes, and increased accumulation of neutrophils in multiple vital organs. Elevated levels of mediators of sepsis-associated vascular dysfunction and hypotension were also detected. These cellular and molecular changes were shown to reflect upregulation of the proinflammatory transcription factors NF-*κ*B and $AP-1$. 15d-PG J_2 and ciglitazone prolong the animals' survival, reversing the sepsisassociated proinflammatory events and improving arterial blood pressure [4]. Likewise, in mice experiencing polymicrobial sepsis, pioglitazone reduces bacterial burden at the site of infection (the peritoneum) and in the blood and alleviates edema and capillary congestion at target tissues such as the lungs by reducing neutrophil infiltration and cytokine accumulation. Survival rate of septic mice consequently improves. The authors found that PPAR*γ* activation exerts its protective effect against bacterial sepsis via an IL-10-dependent reduction in expression of MyD88, a critical downstream component of the TLR pathway [21].

Materials and Methods

Mice

Adult male mice, weighing 25±2 g (supplied by The Field Surgery Institute, Kunming Medical University, Kunming, China), were housed in 12-h light-dark conditions with free access to water and standard laboratory chow. The animal procedures were performed in strict accordance with National Institutes of Health guidelines, which were approved by the Ethics Committee of Department of Medicine, University of Pittsburgh School of Medicine, PA, USA

Reagents

A TRIzol kit was obtained from Gibco-BRL (Carlsbad, CA, USA) and a reverse transcription kit was obtained from University of Pittsburgh School of Medicine. A polymerase chain reaction (PCR) amplification reagent kit and the DNA ladder marker. β-actin was obtained from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA, USA) and tumour necrosis factor-α (TNF-α), interleukin (IL)-6, -1β and -10 enzyme-linked immunosorbent assay (ELISA) kits were obtained from Pierce Biotechnology Inc. (Rockford, IL, USA). Salidroside (99% purity) was acquired from the National Institute for the Control of University of Pittsburgh School of Medicine.

Model and groups

Using a random number table, 77 mice were randomly divided into four groups: Normal control, sham-operation (sham), sepsis model (model) and salidroside treatment (treatment) groups (n=20 per group). The sepsis model was induced by cecal ligation and puncture (CLP). Briefly, the animals were deprived of food, but water was permitted for 6 h prior to surgery. Under light ether anaesthesia, a laparotomy was performed through a midline abdominal incision. The cecum was punctured twice at different sites with an 18-gauge needle and gently compressed until faeces were extruded. The bowel was then returned to the abdomen and the abdominal incision was closed in two layers. Animals in the model and treatment groups were treated with 1.25 ml normal saline per 25 g body weight subcutaneously at the completion of surgery to replace the extracellular fluid sequestered during peritonitis [22]

Animals in the sham group underwent sham surgery, in which the cecum was neither ligated nor punctured. Starting at 8 h prior to surgery, animals in the treatment group were injected with 8 mg/kg salidroside every 8 h, while the animals in the normal control, sham and model groups were administered the same volume of normal saline.

Subsequently, the animals in each group were anaesthetised with ether 24 h post-surgery, and the right internal carotid artery was isolated. Blood was extracted (1 ml), centrifuged to collect the supernatant, dispensed into two sterile tubes, sealed with sealing glue and placed in freezer at −20°C for examination. All the animals were sacrificed 24 h following surgery via anesthesia and tissue samples were collected for further tests.

Extraction of RNA

For the isolation of lung tissue RNA, the mice were humanely sacrificed and under aseptic conditions, the lung tissue was removed and immediately frozen in liquid nitrogen. Prior to RNA extraction, the lung samples were homogenised in TRIzol reagent (Invitrogen, Carlsbad, CA, USA) using a Mixer Mill 301. The total RNA was extracted according to the manufacturer's instructions. The RNA samples were electrophoresed in agarose gel and visualised with ethidium bromide for quality control.

Real-time quantitative PCR

Total cellular RNA was extracted by using the RNeasy RNA extraction kit (Qiagen, Valencia, CA, USA) and Trizol mRNA extraction kit (Thermo Fisher Scientific) according to manufacturer instructions. cDNA was synthesized from 1 μg or 500 ng total RNA by using the SuperScript first-strand synthesis system (Thermo Fisher Scientific), as previously described [22].

Western blotting

Protein extraction, electrophoresis, and gel transfer were performed as previously described [23]. Anti-human PON-2 was purchased from Abcam (Cambridge, MA, USA). Anti-PPARγ was purchase from Cell Signaling Technology (Danvers, MA, USA) and glyceraldehyde 3 phosphate dehydrogenase (GAPDH), which was used as housekeeping gene, was purchased from Santa Cruz Biotechnology. Cell lysates were prepared by using cell lysis buffer (Cell Signaling Technology). ZO-1, claudins-1 and -4, and occludin Abs used for immunoblotting were purchased from Thermo Fisher Scientific.

Histopathological examination

Lung tissue was fixed in 10% formalin for 24 h, which was followed by dehydration. The lung tissue was embedded in paraffin wax, sectioned into 5-μm-thick slices and stained with haematoxylin and eosin. Microphotography of the lung sections was captured with a light microscope (Olympus, Tokyo, Japan). The severity of the ALI was scored in a blind manner, as previously described [24], according to the categorical degree scoring (zero, minimal or no damage; four, severe damage) of alveolar congestion, hemorrhaging, cell infiltration into the airspace or vessel wall and thickness of the alveolar wall. The mean score of five random areas per section per animal was used for data analysis.

Statistical analysis

Quantitative data are presented as the mean \pm standard error of the mean (SEM) of at least three independent experiments. The histological injury scoring data were analysed by analysis of variance (ANOVA) followed by the Kruskal-Wallis nonparametric test for comparison, which was then presented as a box-and-whisker plot. The remaining data were analysed by ANOVA and then with the Newman-Keuls test for comparison. For comparisons among the groups, the unpaired Student's t-test was used (GraphPad Prism, GraphPad Software Inc., San Diego, CA, USA), in which P<0.05 was considered to indicate a statistically significant difference.

Results

Salidroside upregulates the expression levels of PPAR-γ and Iκβ and blocks NF-κβ p65 expression in lung tissue

To assess the potential role of salidroside in CLP-induced ALI, the mRNA and protein expression levels of PPAR-γ, NF-κβ p65 and Iκβ in the lung tissue of the lipopolysaccharide (LPS)-induced ALI mice were determined using qPCR and western blot analysis at 24 h after the CLP challenge. As shown in [Figs. 1](https://www.spandidos-publications.com/10.3892/etm.2014.1629#f1-etm-07-06-1446)–[4](https://www.spandidos-publications.com/10.3892/etm.2014.1629#f4-etm-07-06-1446), the expression levels of PPAR-γ and Iκβ were markedly reduced and the NF-κβ p65 expression levels were markedly enhanced in the model group compared with those in the normal control and sham groups. However, following the administration of salidroside, the expression levels of PPAR-γ and Iκβ were markedly upregulated and NF-κβ p65 expression levels were significantly decreased. In combination, these observations indicated that salidroside may be involved in the increased expression levels of PPAR-γ and Iκβ and the reduced NF-κβ p65 expression levels in CLP-induced ALI. A negative correlation was shown to exist between PPAR-γ and NF-κβ p65 mRNA expression levels, as well as between PPAR-γ and NF-κβ p65 protein (r=−0.452, P<0.05; r=0.613, P<0.05).

Salidroside increases PPAR-γ and Iκβ activation in lung tissue, and inhibits NF-κβ p65 activation in lung tissue

To study the effect of salidroside on the positive expression of PPAR-γ, NF-κβ p65 and Iκβ in CLP-induced ALI, immunohistochemical staining was performed on the lung sections. As shown in [Figs. 2](https://www.spandidos-publications.com/10.3892/etm.2014.1629#f5-etm-07-06-1446) and [3,](https://www.spandidos-publications.com/10.3892/etm.2014.1629#f6-etm-07-06-1446) in the model group, the activation of PPAR-γ and Iκβ was significantly suppressed and the activation of NF-κβ p65 was significantly increased at 24 h after the CLP challenge, as compared with the sham group. However, in the CLP-induced mice that received salidroside, the positive expression levels of PPAR-γ and Iκβ were significantly increased and the NF-κβ p65 positive expression levels were markedly inhibited compared with the model group. Therefore, salidroside may suppress the positive expression of NF-κβ p65 and promote the positive expression of PPAR-γ and Iκβ.

Figure 3

Effect of the administration of salidroside on the PPAR-γ, NF-κβ p65 and Iκβ positive expression levels in the lung tissue of CLP-ALI mice. The groups of rats were challenged with CLP and treated with salidroside 24 h later. Immunostaining was performed on the lung sections following antigen retrieval using Retrievagen A. Representative immunostaining images show the positive expression levels of PPAR-γ, NF-κβ and Iκβ in three groups of mice (immunofluorescence staining; magnification, ×200). Positive expression levels of (A–C) NF-κβ p65 (A, sham surgery group; B, model group; C, treatment group); (D– F) PPAR-γ (D, sham surgery group; E, model group; F, treatment group); (G–I) Iκβ (G, sham surgery group; H, model group; I, treatment group). Salidroside ameliorates the histopathological changes in the lungs of CLP-ALI mice

To determine the effect of salidroside on histological lung injury, histopathological analysis was performed on the lung sections stained with hematoxylin and eosin. Histological analyses of the lungs following CLP exposure revealed a damaged alveolar structure with evident concretions and liquid draining within the bleeding inflammatory cells. In addition, the perivascular gap was widened and there was numerous alveolar stoma that were infiltrated by mononuclear inflammatory cells, including macrophages, plasma cells and neutrophils. The ALI pathology scores also increased significantly compared with that in the normal control and sham groups. The lungs of the mice in the treatment group exhibited less severe damage without significant bleeding

American Journal of BioMedicine AJBM 2014;**2**(4): 228–246 Research Article doi: 10.18081/2333-5106/014-04/228-246

Figure 5.

Administration of salidroside ameliorated the histopathological changes of the lungs in CLP-ALI mice. Histological evaluation of the therapeutic potential of salidroside on CLP-induced lung injury in mice was analysed at 24 h after the CLP challenge (haematoxylin and eosin staining; magnification, ×200). Discussion

The positive effect of PPAR*γ* (and/or its ligands) in bacterial infections, especially its antiinflammatory effects via inhibition of proinflammatory molecules such as IL-6, TNF-*α*, IL-1*β*, and IL-12, has been well documented. In the *ex vivo* study by Aronoff et al., troglitazone, rosiglitazone, and 15d-PGJ² increased the Fc*γ* receptor-mediated phagocytosis of *Klebsiella pneumoniae* as well as that of IgG-opsonized nonphysiological targets by primary lung macrophages abundantly expressing PPAR*γ* [25].

This effect appears to be mediated through PPAR*γ*, demonstrating the role of PPAR*γ* in pathogen clearance during bacterial infections. This phagocytic role of PPAR*γ* is in line with other studies showing that PPAR*γ* activation increases expression of CD36 cell surface receptors and uptake of apoptotic neutrophils by macrophages, a process critical for resolution of inflammation [26]. Likewise, Stegenga et al. reported that the PPAR*γ* ligand ciglitazone alleviates *Streptococcus pneumoniae*-induced lung inflammation in mice by suppressing bacterial outgrowth and proinflammatory cytokine secretion, thereby improving survival of the infected animals [27]. Interestingly, however, contrary to previous findings [28], Stegenga et al. observed no ciglitazone-induced increase in *in vitro* phagocytosis or killing ability of alveolar macrophages in response to *S. pneumoniae* infection [22]. This discrepancy may reflect differences in agonists and pathogens used as well as the cell types employed in their studies. Nevertheless, these studies highlight the role of PPAR*γ* activation in reducing inflammation and improving pathogen clearance.

Anti-inflammatory effects of PPAR*γ* activation are not confined to bacterial infections of the lungs.

In a study using a mouse model of central nervous system infection by *Staphylococcus aureus*, which is associated with brain abscesses in humans, ciglitazone reduced the expression of proinflammatory mediators as well as iNOS and inhibited microglia/macrophage activation. The authors of the study noted that ciglitazone's ability to suppress proinflammatory mediator secretion is only partial, a significant observation as complete absence of proinflammatory responses would result in persistence of bacteria in the brain parenchyma and therefore would be detrimental to survival of the infected animals.

Another key finding in this study was that ciglitazone is capable not only of preventing microglial activation when administered prophylactically but also of dampening the activity of microglia that have already been stimulated by on-going bacterial infections. This is clinically relevant and important because typically patients seeking treatment for brain abscess would already exhibit inflammatory central nervous system responses.

In addition to attenuation of microglial response, ciglitazone-treated animals show reduced bacterial burdens, probably due to the enhanced microglial phagocytic ability that was observed. Moreover, ciglitazone accelerates brain abscess encapsulation, as evidenced by the increased deposition and compact organization of fibronectin as well as the early emergence of *α*-smooth muscle actin-expressing myofibroblasts associated with development of the

doi: 10.18081/2333-5106/014-04/228-246

capsule, which could prevent further dissemination of the pathogens [29]. Altogether, these observations provide evidence that PPAR*γ* activation by synthetic agonists is an attractive therapeutic intervention for brain abscesses since it is capable of achieving a balance between effective clearance of pathogen and minimal damage to the brain tissue.

CLP-induced sepsis with acute suppurative peritonitis has been demonstrated to be a typical sepsis model with Gram-negative bacteria being the predominant source of infection [11]. Gram-negative bacteria release numerous endotoxins and severe endotoxemia may activate the inflammatory cells and cause inflammatory reactions that lead to tissue and organ injury, dysfunction, and possibly mortality.

Lung tissue is one of the most vulnerable tissues to endotoxemia. LPS causes ALI, which further develops into ARDS [6]. In the present study, an endotoxemia rat model was created via the use of CLP to simulate sepsis-related lung injury in order to observe the effect of salidroside on ALI. The experimental results revealed that the rats exhibited varying degrees of lung tissue hyperaemia, haemorrhage, alveolar septal thickening, infiltration of the inflammatory cells and neutrophil accumulation, which are all pathological changes associated with ALI. These observations indicated that the model was successful.

ALI is an uncontrollable pulmonary inflammation caused by large amounts of inflammatory cells and cytokines. Under the effects of CLP, lung macrophages and neutrophils produce proinflammatory cytokines, including TNF-α and IL-1β, triggering the inflammatory reaction cascade [18].

In the present study, the plasma levels of TNF-α, IL-1β, and IL-6 significantly increased 24 h after CLP surgery. When 80 mg/kg salidroside (i.v.) was administered 24 h after the CLPinduced injury, the plasma levels of the proinflammatory cytokines and lung inflammation decreased significantly. In vitro experiments demonstrated that 80 mg/kg salidroside (i.v.) reduced the levels of TNF-α, IL-1β and IL-6 secretion by lung macrophages. IL-10 is one of the most important anti-inflammatory cytokines and salidroside administration markedly increased the IL-10 concentration in the CLP-induced ALI mice.

The administration of salidroside clearly inhibited the production of the proinflammatory cytokines, TNF-α, IL-1β and IL-6, and increased the IL-10 levels. Thus, salidroside improves the homeostasis of the cytokine network and the balance between the inflammatory and antiinflammatory reactions associated with ALI.

PPARs are members of the nuclear receptor superfamily with three isomers existing in mammals: α, β and γ [30]. Steroid, thyroid and retinoid hormones are ligands for the receptors. PPAR-γ is highly expressed in adipose tissue and its activation plays a key role in increasing systemic insulin sensitivity. PPAR-γ agonists are clinically used in the treatment of type 2 diabetes mellitus and metabolic syndrome.

PPAR-γ has been shown to be constitutively expressed in numerous types of tissue, including lung tissue, where it has been hypothesised to play a protective role [31]. In addition, PPAR-γ expression in macrophages and lymphocytes suppresses inflammatory responses, and PPAR-

doi: 10.18081/2333-5106/014-04/228-246

γ agonists inhibit the production of proinflammatory cytokines and regulate the process of inflammation by activating this nuclear receptor [32]. PPAR-γ is a ligand-activated transcription factor, whose activation plays a role in controlling the inflammatory response. Several studies have demonstrated that the activation of PPAR-γ by specific ligands significantly improves survival rates in clinically relevant models of septic shock [33].

The beneficial effect of PPAR-γ activation is likely to be secondary to the inhibition of the production of several inflammatory mediators, as has been shown in vivo in septic rodents [34] and in vitro in activated macrophages and monocytes [35]. Sepsis and other inflammatory states affect the PPAR-γ expression levels and correlate with the inflammatory response. The expression levels of PPAR-γ are downregulated in the lung and vascular endothelium in rodent models of septic shock, and treatment with PPAR-γ ligands reverses the sepsis-induced reduction [36].

In adipose tissue, the expression levels of PPAR-γ decreased after the rats were challenged in vivo with endotoxins and the cytokine-induced suppression of PPAR-γ was reversed with synthetic agonists [7]. However, the mechanisms that lead to a reduction in the levels of PPARγ activity in the presence of sepsis remain unclear. In the present study, CLP blocked PPAR-γ expression in the lung tissue, increasing the levels of proinflammatory cytokines; however, the administration of salidroside enhanced the PPAR-γ expression levels in the lung tissue and inhibited the inflammatory response.

To further characterise the inhibitory effect of salidroside on cytokine production, the present study examined the effects of salidroside on the activation of the transcription factor NF-κβ, which regulates the expression of numerous immune and inflammatory genes and the production of cytokines. NF-κβ is essential for host defence and the inflammatory responses to microbial and viral infections [37], as it is an important transcription factor required for the expression of a number of proinflammatory cytokines [11].

In the majority of cells, NF-κβ exists in an inactive form in the cytoplasm as it is bound to inhibitory Iκβ proteins. Following CLP challenge, NF-κβ is translocated to the nucleus to drive the expression of a variety of inflammatory genes that are involved in the pathogenesis of ALI. Therefore, a blockage of NF-κβ activation and an increase in the Iκβ expression levels is expected to attenuate ALI [23].

This is supported by the results of the present study, which demonstrated that salidroside treatment following the CLP challenge inhibited NF-κβ activation, and the release of inflammatory cytokines promoted the expression of PPAR-γ. This is consistent with the theory that salidroside prevents the release of LPS-induced inflammatory cytokines via its anti-NF-κβ activity, which upregulates PPAR-γ expression levels.

CLP stimulates macrophages, neutrophils and other types of immune cell to produce different mediators, including cytokines such as TNF-α and IL-6, that recruit polymorphonuclear neutrophils to the injured site and contribute to the pathogenesis of ALI and ARDS [38]. Activated neutrophils that release various types of mediators and secrete the elastase enzyme,

Research Article doi: 10.18081/2333-5106/014-04/228-246

whose activity is an indicator of neutrophil accumulation in tissues [12], are recognised to be a primary mechanism in the development of ALI.

In the present study, the interstitial space was shown to be filled with activated alveolar macrophages and neutrophils following the LPS challenge. These pathological changes were reversed by salidroside treatment following the challenge, indicating that salidroside may inhibit LPS-induced leukocyte rolling and transmigration into the lung tissue.

In addition, vascular leakage is a critical pathological process in sepsis [11]. Leakage permits plasma protein and leukocyte extravasation, leading to oedema and inflammatory reactions in the affected tissues [28].

Oedema causes tissue hypoxia, and leukocytes, including neutrophils, cause tissue damage through their excessive production of free radicals and proteases. Thus, vascular leakage is a promising target for the therapeutic treatment of sepsis. In the present study, CLP was found to markedly increase the albumin concentration in BALF, the W/D lung weight ratio and the water content in lung tissue.

Histological analyses of the lungs following CLP exposure revealed a damaged alveolar structure with evident concretions leaking liquid within the bleeding inflammatory cells. In addition, the perivascular gap was widened and there were numerous alveolar stoma infiltrated by mononuclear inflammatory cells. These observations indicated that CLP exacerbates the lung leakage permeability; however, the exacerbated lung leakage permeability was ameliorated by salidroside. These results provide supporting evidence that salidroside posttreatment is effective in reversing LPS-induced lung permeability and injuries.

Conclusions

In contrast to the use of antimicrobial drugs that directly target the problem's source, bacteria, treating infections with immunomodulatory agents such as PPAR*γ* ligands is more complex. The innate immune responses to invading pathogens can be divided broadly into an initial hyperinflammatory stage, termed the systemic inflammatory response syndrome, and a subsequent immunosuppressive stage called the compensatory anti-inflammatory response syndrome.

Thus, immunomodulatory drugs must achieve a fine balance between pro- and antiinflammatory effects on the immune system, dampening excessive systemic inflammatory responses to prevent severe tissue damage and other complications without significantly affecting the essential ability of the host immune system to clear the infection.

We have here reviewed research investigating the effects of PPAR*γ* activation or inhibition during bacterial infections. These studies clearly show that PPAR*γ* is a double-edged sword, possessing both pro- and anti-inflammatory effects and exerting beneficial as well as harmful effects upon host defenses against pathogenic bacteria.

While differences in the type of pathogens, disease models, and PPAR*γ* agonists/antagonists used in the research can explain many of the variations in results reported by different research

American Journal of BioMedicine AJBM 2014;**2**(4): 228–246

Research Article doi: 10.18081/2333-5106/014-04/228-246

groups, timing, the point during the host immune response at which drugs are administered, likely plays a large part in determining which PPARγ agonist/antagonist effect predominates. For instance, blocking the anti-inflammatory cytokine IL-10, which is associated with reduced secretion of proinflammatory mediators, at an early stage of sepsis is detrimental to the host, whereas IL-10 suppression later in sepsis is linked with longer survival of the affected animals. Similarly, established sepsis may respond to immune-stimulating strategies but not to therapeutic interventions designed to suppress proinflammatory mediators secreted early during sepsis. In addition, in human patients, the effect of a PPAR*γ* agonist or antagonist would likely differ with the immune status of each individual—the exact pathophysiologic nature of immune imbalance—as well as other factors such as age, comorbidities, and genetic background.

Patients suffering damage and symptoms due to exaggerated immune response would benefit from the anti-inflammatory effect of PPAR*γ* ligands, while those experiencing immunoparalysisinduced symptoms would require the immune-enhancing effect of PPAR*γ* antagonists to alleviate damage and symptoms.

Thus, it is imperative to aim for a carefully defined balance between immune stimulation and immunosuppression in each patient. Close assessment of the competence of host antimicrobial defenses and the extent of inflammation and tissue injury, including measurement of mediators of the immune response, and adjustment in the dosage and timing of PPAR_{*Y*} agonist/antagonist administration would be valuable for achieving the most desired outcome.
